

Tantalum Barrier Layer for Copper Metallization

RELATED APPLICATION

This application is a division of Serial No. 10/290,746, filed November 7, 2002,
5 issue fee paid, which is a continuation of Serial No. 09/704,161, filed November 1, 2000,
now issued as U.S. Patent 6,498,091.

FIELD OF THE INVENTION

The invention relates generally to processes for formation of vertical interconnects
in integrated circuits. In particular, the invention relates to a tantalum barrier layer for
10 copper metallization.

BACKGROUND ART

Modern integrated circuits include several levels of metallization formed over the
active semiconductor circuitry formed in the substrate, most commonly a silicon wafer.
The multiple metallization layers are required to interconnect the millions to tens of
15 millions of discrete semiconductor devices formed in a single integrated circuit. For
advanced microprocessors, there may be five or more levels of metallization.

Each metallization layer includes a dielectric layer, for example, of silicon dioxide
or possibly a low-k dielectric material deposited over the previous layer, a via (or contact)
hole etched through the dielectric layer, and a metallization including a vertical metallic
20 plug filled into the hole and a horizontal interconnect formed on top of the dielectric
layer.

The formation of vias has become increasingly crucial with the continuing
shrinkage of critical dimensions and the transition to copper rather than aluminum
interconnects. Contacts to underlying silicon will for the most part not be explicitly
25 described hereafter but can equally benefit from the various aspects of the invention.

A generic via is illustrated in the cross-sectional view of FIG. 1. It includes a lower dielectric layer 12 (which in the case of a contact is a silicon-containing layer) having formed therein a conductive feature 14, such as another metallization or, in the case of a contact, a contact region of a transistor. An upper level dielectric layer 16
5 overlies the lower dielectric layer 12 and the conductive feature 14. Advanced plasma etching processes etch a via hole 18 through the upper dielectric layer 16 to the vicinity of the conductive feature 14. This explanation avoids many details about etch stop layers, horizontal interconnects, and advanced structures, particularly including dual damascene, but the fundamental concepts for the invention remain the same.

10 Prior to filling metallization into the via hole 18, the hole is lined with a barrier layer 20 to prevent the diffusion of aluminum or copper into the dielectric 16, which would short out the dielectric between neighboring via, or the diffusion of oxygen from the dielectric 16 into the metallization, which reduces the conductivity of the plug. Only thereafter is a metallization plug 22 filled into the via hole 18. In the case of copper
15 metallization, the filling process typically includes a physical vapor deposition or sputtering (PVD) deposition of a copper seed layer followed by an electrochemical plating (ECP) of copper into the hole.

The barrier structure has become increasingly important as the lateral critical dimension has shrunk to $0.25\mu\text{m}$ and below while the vertical dimension has remained
20 virtually static at between 0.7 and $1.5\mu\text{m}$. As a result, the aspect ratio of the via hole 18 has increased, and the electrical resistance of the vertical electrical metallization has become increasingly important. This emphasis on reduced vertical impedance has been further heightened by the substitution of copper for aluminum as the most desired metallization since copper has a lower bulk resistivity. However, the controlling
25 parameter is the total resistance along a path, including the resistance through the bottom barrier layer portion 24 at the bottom of the via 18. Particularly in the case of an inter-metal dielectric between two metallizations of the same metal, there is no need to include the bottom barrier layer portion 24 since the copper or other metal in the via 22 will be contacting a same metal in the conductive feature 14.

30 In U.S. Patent 5,985,762, Geffken et al. have disclosed directionally etching away

the barrier layer exposed on horizontal surfaces of a copper dual-damascene structure but leaving the barrier layer on the sidewalls to protect the dielectric sidewalls from copper sputtered from the underlying copper feature. This process requires presumably a separate etching chamber. Furthermore, the process deleteriously also removes the
5 barrier at the bottom of the trench in a dual-damascene structure. They accordingly deposit another conformal barrier layer, which remains under the metallized via.

In commonly assigned U.S. Patent Application, Serial No. 09/518,180 filed March 2, 2000, now issued as U.S. Patent 6,277,249, Gopalraja et al. have suggested that a self-ionized plasma sputter deposition of a copper seed layer for a copper metallization 22 can
10 be used to remove the bottom barrier layer portion 24.

Accordingly, it is desired to provide a structure and method of making it which reduces the contact resistance at the bottom of a via.

It is further desired to provide such structure and method without unduly complicating the integrated circuit fabrication process.

15 SUMMARY OF THE INVENTION

One aspect of the invention includes removing a barrier layer formed at the bottom of a via by a sputter etching process performed in a plasma sputter deposition chamber. The same sputter deposition chamber may advantageously be used to then deposit a second barrier layer.

20 The invention also includes the aspect of removing the barrier layer at the bottom of the via and simultaneously depositing a second barrier layer on vertically extending sidewalls.

Another aspect of the invention includes removing the barrier layer at the bottom of the via while not removing the barrier layer from some other horizontally extending
25 surfaces. The selective removal can be effected by simultaneously sputter depositing a second barrier layer on these other horizontal surfaces. The selective deposition of the second barrier layer can be advantageously followed by the sputter deposition in the same sputter reactor of another layer of the second barrier layer under different conditions such that the additional layer is also deposited on the via bottom.

The combined process may be performed in an inductively coupled plasma sputter reactor in which, during the removal step, the sputtering target is not energized and thus not sputtered, but, during the deposition of the second barrier layer, it is energized to be sputtered. During the removal step, the inductive coil generates a plasma of the sputtering working gas, and the wafer is biased to attract the working gas ions.

The invention includes structures achievable by the invention in which a barrier layer is coated on the sides of the hole but not its bottom. It also includes a dual-damascene structure in which the barrier is coated on the trench floor but not on the via bottom.

10 BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a cross-sectional view of a generic via structure of the prior art.

FIG. 2 is a cross-sectional view of a via structure coated with a CVD barrier layer.

FIG. 3 is a cross-sectional view of the via structure of FIG. 2 with the bottom portion of the CVD barrier layer being removed in a PVD chamber.

15 FIG. 4 is a cross-sectional view of the via structure of FIG. 3 further coated with a PVD barrier layer.

FIG. 5 is a cross-sectional view of the via structure of FIG. 4 coated with a copper seed layer and then electro-chemically filled with copper.

20 FIG. 6 is a cross-sectional view of the vis structure of FIG. 5 after completion of the inter-level dielectric level by chemical mechanical polishing.

FIG. 7 is a cross-sectional view of a via structure with the CVD barrier being removed from the bottom of the via at the same time that a first PVD barrier layer is deposited at least on the via sidewalls and possibly in the field area over the top of the dielectric.

25 FIG. 8 is a cross-sectional view of the via structure of FIG. 7 with the further deposition of a second PVD barrier layer.

FIG. 9 is a cross-sectional view of the via structure of FIG. 8 after completion of copper metallization.

FIG. 10 is a cross-sectional view of a dual-damascene structure after deposition of

the barrier and seed layers.

FIG. 11 is a cross-sectional view of the structure of FIG. 10 after electroplating and chemical mechanical polishing.

FIG. 12 is a flow diagram of an integrated process liner deposition process.

5 FIG. 13 is schematic plan view of an integrated tool capable of performing the integrated process of FIG. 12.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

It has been found useful to form a via barrier in two chambers. The first step is performed in a CVD (chemical vapor deposition) chamber in which a CVD barrier layer 10 30, as illustrated in the cross-sectional view of FIG. 2, is first deposited having a composition of titanium silicon nitride (TiSiN). Again, the illustrated structure ignores features such as etch stop layers and dual-damascene holes. The CVD barrier layer 30 may be formed by a three-step process in the TxZ plasma CVD reactor, available from Applied Materials, Inc. of Santa Clara, California. Zhao et al. describe a version of this chamber and a TiN deposition procedure in U.S. Patent 5,846,332. In the first step, a TiN 15 layer is deposited to a thickness of about 5nm by a well known process of thermal chemical vapor deposition at about 350°C using tetrakis-dimethyl-amido titanium (TDMAT) as the precursor gas. Koai et al. describe an alternative plasma CVD process and chamber in U.S. Patent 6,106,625. The thermal CVD is followed by a plasma 20 treatment in the same chamber of the wafer held at 350°C. The same chamber is used for the third step of a thermal soak of the wafer in the presence of silane (SiH₄) to convert the TiN to TiSiN. The CVD process is nearly conformal and coats the sidewalls and bottom of the via hole including a CVD barrier bottom portion 32, a CVD barrier sidewall portion 34, and a CVD barrier field portion 36 on top of the dielectric layer 16.

25 Following the formation of the CVD barrier layer 30, the substrate is transferred to a physical vapor deposition (PVD) chamber in which a tantalum target is used as the sputtering target. The PVD chamber should be one which is capable of producing a relatively high ionization fraction of sputtered atoms, for example, above 10%. The chamber preferably also has the capability of biasing the pedestal electrode supporting the

electrode. Typically, the biasing involves applying an RF bias signal, for example, at 13.56MHz to the pedestal electrode. The RF power creates a negative DC bias on the pedestal and thus accelerates positively charged sputtered metal ions to the wafer.

One reactor satisfying these requirements is the Endura IMP (ion metal plating) sputter reactor available from Applied Materials. This reactor uses an inductive coil to couple RF power into a remote plasma source region. This reactor operates at relatively high argon pressures of about 20 milliTorr to produce a large volume of a high-density plasma, that is, one having an ionization fraction of at least 10^{11}cm^{-3} . Metal ionization fractions may exceed 50% or even 75% in an IMP reactor.

Two other reactors being developed by Applied Materials can also be used for the process of the invention. Both are more conventional DC diode magnetron reactors not relying on RF inductive coupling to create the plasma. Various techniques are used to create a relatively high density plasma in a small portion of the target. The magnetron is scanned over the back of target to provide the required uniformity. Both these reactors can be operated at relatively low pressures of about 1 milliTorr or somewhat less. Their metal ionization fractions are somewhat lower, in the 10% to 50% range. Fu describes an SIP (self-ionized plasma) reactor in U.S. Patent Application 09/373,097, filed August 12, 1999, now issued as U.S. Patent 6,183,614. This reactor uses a flat target and a small unbalanced magnetron having a strong magnetic pole of one polarity surrounding a weaker magnetic pole of the other polarity. Praburam et al. describe an SIP^+ reactor in U.S. Patent Application, 09/518,180, filed March 2, 2000, now issued as U.S. Patent 6,277,249. This reactor includes a target having a large annular groove or vault formed in its side facing the wafer. Various magnets are placed adjacent to the sidewalls and roof of the vault. Very high plasma densities are formed within portions of the vault, thereby increasing the metal ionization fraction.

According to the invention, the same PVD chamber performs two steps. The first step has the effect of removing the CVD barrier layer at the bottom of the via hole, and the second step completes the deposition of the PVD barrier layer. Two embodiments of the two-step process will be described. In the first embodiment, the first step deposits no material and only sputters the CVD barrier layer. In the second embodiment, the first step

combines removal at the bottom of the via hole and deposition of some PVD barrier material in areas other than the bottom of the via hole.

In the first embodiment, particularly as practiced in an IMP chamber configured for sputter deposition of a barrier layer, an argon plasma is formed and the pedestal
5 electrode is RF biased to create a significant negative DC self-bias to strongly attract the argon ions to the pedestal. The IMP chamber allows the formation of an argon plasma without sputtering the tantalum target by exciting the plasma through the inductive coil and not significantly DC biasing the target. The highly directional high-energy argon ions incident on the wafer remove or sputter the CVD barrier bottom and field portions 32, 36.
10 That is, a sputtering process is performed on the wafer, not a sputter deposition process. However, the argon ions do not remove the CVD barrier sidewall portion 34, as illustrated in the cross-sectional view of FIG. 3, because the ions are mostly traveling parallel to the sidewall. In fact, some of the barrier material sputtered from the CVD barrier bottom portion 32 will deposit on the sidewall. Further, the argon ions may even
15 slightly etch into the exposed face 38 of the underlying metallic feature 14. The etching of the metallic feature 14 may be advantageous as a pre-cleaning step to remove any oxide that has spontaneously formed there. The removal of the CVD barrier bottom portion 32 at the bottom of the via hole 18 is advantageous because the TiSiN CVD bottom barrier would increase the contact resistance between the plug to be formed in the
20 via hole 18 and the conductive feature. Gopalraja et al. have described in the above cited patent application a similar sputter removal of a barrier layer during sputter deposition of a copper seed layer.

Thereafter, in a second step performed in the same barrier PVD reactor, a PVD barrier layer 40 is sputter deposited, with the chamber conditions adjusted to produce a
25 sufficiently high energy in the sputtered metal ions that they coat not only the top of the dielectric layer 16 but also over the CVD barrier layer 30 on the sidewalls of the via hole 18 (although the sidewall coverage is small), and at the bottom of the via hole 18 in direct contact to the metallic feature 14. The second step preferably at least begins with the sputter deposition of tantalum or other barrier metal. The second step may include a
30 subsequent deposition of tantalum nitride by admitting nitrogen into the plasma reactor to

effect reactive sputtering.

Exemplary process conditions for the two steps are presented in TABLE 1 for the IMP reactor.

	Step 1	Step 2
Target Power (kW)	0	1
Coil Power (kW)	1	2.5
Pressure (milliTorr)	1	38
Wafer Bias Power (W)	600	350
Bias Duty Cycle (%)	100	50

TABLE 1

These parameters show that the IMP chamber is being operated in the wafer pre-clean mode in the first step and in an ionized sputter deposition mode in the second step.

The wafer is then moved to a copper PVD chamber for deposition of a thin copper seed layer 44, illustrated in the cross-sectional view of FIG. 5. The copper seed layer 44 is needed to act as an electrode for the subsequent electro-chemical plating (ECP) of copper and to nucleate the ECP copper. The copper seed layer 44 is preferably performed in either an IMP reactor, a SIP reactor, or a SIP⁺ reactor although other sputter reactors may be satisfactory. Thereafter, the via hole is filled and overfilled with a copper layer 46 deposited by an ECP process. The excess copper as well as most typically the field portions of the various barriers are removed by chemical mechanical polishing (CMP), which stops on the hard dielectric 16 to produce the structure of FIG. 6. It is assumed that a dual-damascene or similar interconnect structure is used so that the remaining metal 48 acts both as a via to the underlying metallic feature 14 and as a horizontal interconnect just below the surface of the dielectric layer 16.

In the SIP and SIP⁺ sputter reactors as currently configured as well as in other typical diode reactors, the target needs to be powered to create a plasma. In the case of a Ta/TaN barrier, tantalum is being sputtered from the target in the first step. However, it is possible to divide the tantalum sputtering into two steps, the first producing tantalum ions having high energy, the second producing tantalum ions having lower energy so that the first step operates in the sputter removal mode with respect to the wafer while the second step operates in the sputter deposition mode. But, the geometry of the via hole makes the situation more complex.

In the first step, chamber conditions are adjusted to produce tantalum ions having relatively high energies as they are attracted to the wafer to deposit, as illustrated in the cross-sectional view of FIG. 7, a first PVD barrier layer 70, typically of tantalum for copper metallization. As a result, the ions that are attracted to the bottom of the via 18 have such high energy that, not only do they not deposit on the bottom, they sputter away the underlying CVD barrier bottom portion 32 of FIG. 2 and may even slightly etch into the exposed face 38 of the underlying metallic feature 14. With the finite tantalum ion flux, a sidewall portion 74 of the first PVD barrier layer 70 is formed on the sides of the via hole 18, partially from the metal ions reflected off the via bottom. The situation in the field area atop the dielectric layer 16 is more complex. If the tantalum ion fraction is high and the ion energy is sufficiently high, then the field portions of the first PVD barrier layer 70 does not form and instead the field portion 36 of the CVD barrier is removed. However, in SIP and SIP⁺ sputtering, it is possible to balance the ion and neutral fractions. The neutral fraction does not reach the protected bottom of the via hole but does reach the field region with modest energy because they are not affected by pedestal biasing. Therefore, they can deposit on the field region more quickly than the energetic ions are removing material there. Therefore, it is possible to achieve a net deposit of the first PVD barrier layer 70 over the field area. Gopalraja et al. have described in the above cited patent application a similar sputter removal of a barrier layer during sputter deposition of a copper seed layer.

Thereafter, in a second step of the PVD barrier deposition, a second PVD barrier layer 80, illustrated in FIG. 8, is deposited in the same PVD chamber with the chamber

conditions adjusted to produce a lower energy for the sputtered metal ions. With the lower energies, the second PVD barrier layer 80 forms with a bottom portion 82, a sidewall portion 84, and a field portion 86. The second step preferably at least begins with the sputter deposition of tantalum or other barrier metal. The second step may include a subsequent deposition of titanium nitride by admitting nitrogen into the plasma reactor to effect reactive sputtering.

In the first step, chamber conditions are adjusted to produce tantalum ions having relatively high energies as they are attracted to the wafer to deposit, as illustrated in the cross-sectional view of FIG. 7, a first PVD barrier layer 70, typically of tantalum for copper metallization. As a result, the ions that are attracted to the bottom of the via 18 have such high energy that, not only do they not deposit on the bottom, they sputter away the underlying CVD barrier bottom portion 32 of FIG. 2 and may even slightly etch into the exposed face 38 of the underlying metallic feature 14. With the finite tantalum ion flux, a sidewall portion 74 of the first PVD barrier layer 70 is formed on the sides of the via hole 18, partially from the metal ions reflected off the via bottom. The situation in the field area atop the dielectric layer 16 is more complex. If the tantalum ion fraction is high and the ion energy is sufficiently high, then the field portions of the first PVD barrier layer 70 does not form and instead the field portion 36 of the CVD barrier is removed. However, in SIP and SIP⁺ sputtering, it is possible to balance the ion and neutral fractions. The neutral fraction does not reach the protected bottom of the via hole but does reach the field region with modest energy because they are not affected by pedestal biasing. Therefore, they can deposit on the field region more quickly than the energetic ions are removing material there. Therefore, it is possible to achieve a net deposit of the first PVD barrier layer 70 over the field area. Gopalraja et al. have described in the above cited patent application a similar sputter removal of a barrier layer during sputter deposition of a copper seed layer.

Thereafter, in a second step of the PVD barrier deposition, a second PVD barrier layer 80, illustrated in FIG. 8, is deposited in the same PVD chamber with the chamber conditions adjusted to produce a lower energy for the sputtered metal ions. With the lower energies, the second PVD barrier layer 80 forms with a bottom portion 82, a

sidewall portion 84, and a field portion 86. The second step preferably at least begins with the sputter deposition of tantalum or other barrier metal. The second step may include a subsequent deposition of titanium nitride by admitting nitrogen into the plasma reactor to effect reactive sputtering.

5 Several methods are available to control the metal ion energy. Increasing the RF bias applied to the pedestal electrode through a coupling capacitor will increase the magnitude of the negative DC self-bias and thus increase the energy of the metal ions. At least in the case of SIP and SIP⁺, either decreasing the chamber pressure or increasing the target power will also increase the DC self-bias. Thus, the second PVD sputtering step
10 should be performed at lower bias power, higher pressure, or lower target power than is the first PVD sputtering step. Of course, adjustment of some combination of the three controls can be used.

 The previously described steps associated with deposition of the copper seed layer, electroplating of copper, and chemical mechanical polishing are similarly
15 performed to produce the structure of FIG. 9, which differs from that of FIG. 6 by the addition of the sidewall portion of the first PVD barrier layer 70.

 The SIP and SIP⁺ sputter reactors allow tuning of not only the metal ion energy but the ratio of ions to neutrals. This tunability allows the possibility of very selective removal of the first barrier layer at only the bottom of the via in a dual-damascene
20 structure, as illustrated in the cross-sectional view of FIG. 10. A multi-step etching process is used to etch a dual-damascene hole in the upper dielectric layer 16 including a via hole 90 for connecting to the underlying copper feature 14 and a trench 92 providing horizontal interconnects. Usually, there are multiple via holes 90 and corresponding
25 underlying copper features 14. The underlying copper feature 14 may be a copper-filled trench in the lower metallization level. The trench 92 may have a lateral size only slightly larger than the diameter of the via hole 90, but it typically has a substantially longer length. Etch stop layers and underlying barrier layers are not illustrated.

 The CVD barrier layer 30 is conformally deposited over the horizontal and vertical surfaces of the via hole 90 and trench 92 as well as over the field area on top of
30 the upper dielectric layer 16. A first PVD sputtering step with energetic metal ions is

used to remove the CVD barrier layer 30 at the bottom of the via holes while depositing a first PVD barrier layer 70 over the CVD barrier layer 30 on the via sidewall 94, the trench floor 96, the trench sidewalls 98, and field area 100 on top of the dielectric layer 16. The differential deposition, particularly on horizontal surfaces, can be achieved because the
5 very narrow access to the high-aspect ratio via hole 90 admits very few neutral metal atoms to the bottom of the via hole 90, and instead the energetic metal ions etch the CVD barrier layer 30 at the via bottom. On the other hand, the trench floor 96 is slightly more exposed in its lateral direction and significantly more exposed in its axial direction. As a result, a substantial number of the neutral metal atoms reach the trench floor 96 and
10 attempt to deposit there. On net, the deposited neutrals prevent the energetic metal ions from significantly etching the underlying CVD barrier layer 30 on the trench floor 96. The field areas of the CVD barrier layer 30 are even more exposed to the neutral metal atoms, and a thicker first PVD barrier layer 70 grows there. A second PVD sputter step preferably performed in the same PVD chamber coats a second PVD barrier layer 80 over
15 the entire exposed surface, including the bottom of the via hole 90.

Gopalraja et al. describe a similar sputter etch and sputter deposition process in U.S. Application, Serial No. 09/703,601, now issued as U.S. Patent 6,451,177, incorporated herein by reference in its entirety.

Thereafter, the copper seed layer (not illustrated here) is deposited, copper is
20 electroplated into the via and trench and over the top of the trench, and the structure is chemical-mechanically polished down to the dielectric layer 16 to produce the metallized dual-damascene structure of FIG. 11, in which a copper metallization 102 fills both the via 90 and the trench 92. This structure is advantageous over that possible with the barrier removal of Geffken et al. in that the trench floor is protected by a complete set of
25 barrier layers preventing vertical diffusion between the oxide layer 16 and copper metallization 102.

The steps described above are part of an integrated process for forming a liner in hole penetrating through a dielectric layer. The process flow is presented in the flow diagram of FIG. 12 and can be performed on a single integrated tool such as that
30 illustrated in FIG. 13. Before entering the system, the via hole is etched through the

uppermost dielectric layer down to the underlying metallic feature. The etch may form a dual-damascene structure and involve a more complex structure for the dielectric layer. After the wafer enters the system, in step 110 the wafer is degassed. This operation is usually combined with an orientation step to orient the orientation indicia on the wafer in a predetermined direction. In step 112, the wafer is pre-cleaned by a process including
5 subjecting the wafer to an argon plasma formed by a remote inductive coil with a chamber pressure of about 0.5 Torr with about 300W of RF bias applied to the pedestal electrode. This soft plasma etch removes spontaneous oxidation and other contaminants from the exposed surface.

10 In step 114, a CVD barrier layer is deposited, typically composed of TiN or TiSiN. As described before, the CVD barrier layer nearly conformally coats the sidewalls and bottom of the via hole as well as the field area on top of the dielectric layer.

Step 116 is a PVD operation that removes the CVD barrier layer at the bottom of the via. Depending upon the sputter chamber being used and the precise process
15 parameters, the first PVD barrier sputter step may coat a first PVD barrier layer on the via sidewalls and possibly on the field area. In a process tuned for dual damascene the first barrier PVD step removes the CVD barrier layer only at the bottom of the via hole but coats the first PVD barrier layer on the trench floor and in the field area. Step 118 sputter deposits another PVD barrier layer on all exposed surfaces including the via bottom, via
20 sidewalls, and field area as well into surfaces of the trench or trenches if any. For a copper metallization, if the first barrier PVD step 116 net deposits the barrier, it is preferably a metallic tantalum deposition. In either case, at least an initial part of the PVD barrier layer deposited in the second barrier PVD step 118 is preferably composed of tantalum. Optionally, a second part of the second PVD barrier layer is composed of
25 tantalum nitride formed by admitting nitrogen into the PVD reactor. The two barrier PVD steps 116, 118 are preferably performed in the same plasma sputter reactor having a tantalum or other barrier metal target.

Finally, a copper seed layer is deposited in step 120, after which the wafer having a complete liner formed thereon is removed from the system. Subsequent steps of
30 electro-chemical plating (ECP) and chemical mechanical polishing (CMP) are performed

elsewhere to complete the inter-level metallization. It is also appreciated that the invention does not require ECP or CMP, but may instead use more conventional sputter filling of the via and/or metal lithography of the horizontal interconnects. It is further appreciated that the liner process is not restricted to copper metallization, and the process
5 may be adapted to aluminum metallization.

The integrated process of FIG. 12 may be practiced on an integrated tool, such as the Endura tool illustrated in schematic plan view in FIG. 13 and available from Applied Materials, Inc. The system includes two central vacuum transfer chambers 124, 126 which are interconnected through vacuum locked pass through stations 128, 130 and each
10 of which contains a wafer robot 132, 134 capable of reaching any of multiple stations arranged around the periphery of the respective transfer chambers 124, 126.

Wafers are loaded into and out of the first transfer chamber 124 through wafer cassettes contained in load lock chambers 136, 138. Upon entry, an orient/degas chamber 142 rotates the wafer to the correct orientation and heats it sufficiently to degas it. A
15 pre-clean chamber 144 then subjects the wafer to an argon plasma pre-cleaning.

The wafer is then transferred to the second transfer chamber 126, which is typically held at a higher vacuum than the first transfer chamber 124. A CVD chamber 148 deposits the CVD barrier layer. A PVD chamber 150 may be used for both PVD steps, both the first one operating to remove material on the via bottom and a second one
20 with a lower ion energy to produce net deposition. If desired, the same chamber can be used for reactive sputtering of a nitrided barrier layer. For copper metallization, the PVD chamber 150 typically has a tantalum target. A second PVD chamber 152 is used to deposit the copper seed layer. Thereafter, the wafer with its liner layer completely formed is returned through the first transfer chamber 124 to a cassette in one of the load locks
25 136, 138. It is appreciated that for higher throughput the empty space on the second transfer chamber 126 can be used for a second CVD barrier chamber 148 or a second PVD barrier chamber 150 depending on their relative processing rates.

A controller 154 is loaded with a process recipe through a removable recording medium 156 and controls the operation of the entire integrated tool.

30 Although the invention has been described in context of the first barrier layer

being deposited by a CVD method, the invention is applicable to structures using first barrier layers deposited by other methods. Atomic layer deposition (ALD) is a process for depositing the barrier one atomic layer at a time. In another example, a first sputtered barrier layer may comprise a first refractory metal, and a second sputtered barrier layer
5 may comprise a second refractory metal requiring another sputter reactor.

It is appreciated that the various barrier layers may be based on different materials than those discussed. The most common barriers are based on the refractory metals titanium, tantalum, and tungsten and their nitrides, but other barriers are possible.

Accordingly, it is seen that the same sputtering chamber can be used for distinctly
10 different effects of removing restricted portions of a liner layer as well as coating over the liner layer and other exposed portions.
